**Abstract**

Afferent Loop Syndrome (ALS) is a complication caused by obstruction of the biliopancreatic limb after gastrointestinal reconstruction. Re-operation is preferred in surgically fit patients, but higher-risk patients have limited surgical options. We present a case of ALS secondary to duodenal cancer recurrence after a Whipple procedure, treated successfully with the novel Endoscopic Ultrasound-guided Gastrojejunostomy stent placement (EUS-GJ).

**Keywords:** Axios stent; Afferent loop syndrome; Duodenal cancer

**Introduction**

Afferent loop is the duodenojejunal loop proximal to gastrojejunal anastomosis that carries biliopancreatic contents. Afferent Loop Syndrome (ALS) occurs when an intrinsic or extrinsic obstruction causes partial or complete blockage of the afferent loop. Increased intraluminal pressure in ALS causes severe abdominal pain, nausea, vomiting, and occasionally, bowel ischemia [1]. Surgical reconstruction is the preferred treatment, but in high-risk surgical patients, endoscopic placement of an enteral stent is an alternative [2,3]. Endoscopic Ultrasound-guided Gastrojejunostomy stent placement (EUS-GJ) is a novel technique that allows endosonographic localization of the jejunum from inside the stomach and placement of a lumen-opposing stent across the newly created fistulous tract [3,4].

**Case Presentation**

A 60-year-old man initially presented with a resectable duodenal adenocarcinoma with pancreatic invasion. He underwent a Whipple procedure complicated by a pancreatic anastomotic leak that improved with non-surgical management. The patient later developed pulmonary embolism and was started on oral anticoagulation with IVC filter placement. Adjuvant chemotherapy with FOLFOX was started after, but discontinued due to severe abdominal pain, persistent nausea, anorexia and upper gastrointestinal bleeding. Computerized Tomography (CT) Abdomen revealed multiple hypodense hepatic lesions concerning for metastasis, a solid mass in the pancreatic bed suspicious for local recurrence and evidence of a distended afferent loop proximal to the area of local recurrence, with decompressed bowel distally (Figure 1A). Subsequent CT-guided biopsy of the liver lesions revealed metastatic adenocarcinoma of duodenal origin. After a multidisciplinary discussion, we decided to first try decompression by endoscopic or percutaneous approaches to avoid surgical morbidity due to his advanced malignancy. Our goal was to palliate his symptoms and allow him to restart systemic chemotherapy. The first attempt to place an intraluminal stent endoscopically failed because the afferent limb was significantly looped, preventing us from reaching the area of obstruction. The alternative was to use EUS-GJ from the stomach to the obstructed afferent loop. Although this technique has not been well-studied in these situations, it seemed viable as our patient’s afferent loop was dilated and fluid-filled. Moreover, the distance between the stomach and loop seemed appropriate on CT imaging (Figure 1B). Subsequent CT-guided biopsy of the afferent loop revealed metastatic adenocarcinoma of duodenal origin. After creating the fistulous tract and deploying the stent, a large amount of bile was seen gushing through the
The stent was cannulated using a 5.5 cm CRE 15 mm balloon, with dilation performed at 15 mm and held for 1 min (Figure 2B). Within 24 h post-procedure, the patient’s symptoms had improved significantly. He was allowed a clear liquid diet, which he tolerated well. A follow-up CT abdomen demonstrated decompression of the obstructed loop with a stent in place without evidence of intra-abdominal complications (Figure 3). He was discharged three days later and the stent was left in place for 8 weeks to allow therapeutic fistula formation before removal.

**Discussion**

EUS-GJ is a novel fully-endoscopic procedure that allows us to create a functional anastomosis decreasing the risks of surgical intervention. Axios stent use for ALS was first described by Shah et al. in 2015 and has since been adopted by others [2,5,6]. Success rates using this technique ranges from 90% to 100% [7,8]. However, complications have been reported in up to 40%, highlighting the importance of a multidisciplinary approach with surgical backup [9]. The use of endoscopic ultrasound to localize the target bowel, cautery for fistula tract creation, and the self-expanding stent are novel features that improve its safety and success rates. However, examination of large series is needed to better understand its risks and potential complications. Localization of the target bowel or jejunum can be challenging but in ALS, target identification is usually straightforward because the loop tends to be fluid-filled and distended. If the target loop is not distended, intraluminal assisted methods such as dedicated balloon catheters inflated with saline or contrast, nasobiliary drain catheters, or jejunal distention using a 22-gauge needle for saline injection could be used [3]. Nevertheless, these methods may increase risk of complications and their success depends greatly on user experience. Another potential problem after target localization is misplacement of the lumen-apposing stent. Tyberg et al. reported a 27% rate of misplacement, the only reason for technical failure overall [3]. When the target is a fixed organ like in pancreatic pseudocyst cases, misplacement seems to be lower than when dealing with mobile targets such as small bowel. ALS secondary to malignancy or local recurrence after a Whipple procedure,
like in our case, has been reported in 13% of patients, especially those who survive three years or longer following surgery [10-12]. In cases of ALS secondary to unresectable malignancy, palliative approaches remain the mainstay of treatment. There are different methods to deal with ALS in these cases. Pannala et al. reported 24 patients with ALS in pancreatic cancer, 63% underwent endoscopic inventions including 3 balloon dilations, 8 double-pigtail stents traversing the afferent limb stricture, 1 balloon dilation and double-pigtail stent placement, 1 afferent limb metal stent placement, and 2 biliary stent placements [10]. Those who did not receive endoscopic interventions underwent percutaneous transhepatic biliary drainage or a rendezvous procedure for afferent limb strictures at multiple sites, while those with obstructive jaundice or cholangitis underwent percutaneous biliary and luminal drainage by catheter placement in the proximal afferent limb [10]. Novel endoscopic procedures, like the one presented here, have encouraging success rates with lower complications than previously mentioned procedures. In our patient, multidisciplinary collaboration helped us identify innovative potential endoscopic solutions that allowed us to avoid more morbid surgical interventions. A team experienced in this advanced technique in collaboration with a surgical team is crucial to identifying patients who could potentially benefit from this procedure [13,14].
