Keywords
Dural arteriovenous fistula; Torcular DAVF; Supracerebellar approach; Suboccipital mini craniectomy

Abbreviations
CT: Computed Tomography; CTA: Computed Tomographic Angiography; DAVF: Dural Arteriovenous Fistula

Background
Intracranial Dural Arteriovenous Fistulae (DAVF) account for about 10% to 15% of all intracranial arteriovenous lesions [1]. DAVFs of the posterior fossa can present with either acute hemorrhage, pulsatile tinnitus or symptoms depending on their drainage pattern including intracranial hypertension, cerebral edema, and hydrocephalus and cranial nerve palsies [2].

Case Description
We present a case of a 58-year-old male who presented to our department with sudden-onset severe headache and nuchal rigidity. There was no altered level of consciousness. CT scan revealed intraparenchymal hemorrhage into the left cerebellar lobe; CTA identified the source as a ruptured torcular DAVF. Digital subtraction angiography further defined the DAVF as type IV according to Cognard classification, supplied by transosseous branches of the left occipital artery and draining retrogradely into the inferior vermian vein. Emergency endovascular embolization was attempted; however sufficient occlusion was not achieved. The patient therefore underwent...
a left lateral suboccipital mini craniectomy in the prone position, whereupon successful clip ligation of the DAVF was achieved through the supracerebellar route. The patient’s postoperative course was uneventful without complications or any neurological deficit. Postoperative angiography revealed complete obliteration of the DAVF without residual arteriovenous shunting.

**Conclusion**

Torcular DAVFs are rare lesions located at the midline of the posterior margin of the falciotentorial junction. Surgical disconnection of the draining vein at its origin is feasible through suboccipital mini craniectomy providing complete occlusion of the dural arteriovenous fistula.
