Abstract

Internal Hernia (IH) is a rare cause of Small Bowel Obstruction (SBO) associated with a high risk of strangulation and mortality if left untreated. Due to increasing complex abdominal surgeries, the incidence of acquired IH has also increased over the years as opposed to congenital IH that remain relatively unchanged. Regarding the several types of IH, congenital transmesocolic hernia of the transverse colon is a very rare type with only few cases previously reported in the literature.

We here report the case of a 77-year-old female patient who presented to our emergency department with an acute abdominal pain and vomiting. The plain abdominal radiograph demonstrated signs of SBO and the abdominal computed tomography revealed findings highly suggestive of an IH. A congenital transmesocolic hernia of the transverse colon was confirmed on laparotomy with reduction and closure of the defect leading to full recovery of the patient. In this case report, the clinical pictures and radiological features are highlighted together with a review of the literature.

Although CT is currently the mainstay imaging in the workup of SBO, its accuracy to preoperatively diagnose and distinguish among several types of IH remain rather low. Thus, when an IH is suspected, prompt surgical management can avoid bowel ischemia and reduce complications. A high conversion rate to an open approach is often needed due to work space limitations.

Keywords: Transverse transmesocolic hernia; Congenital internal hernia; Small bowel obstruction

Abbreviations

ARDS: Acute Respiratory Distress Syndrome; CRP: C-Reactive Protein; CT: Computed Tomography; IH: Internal Hernia; SBO: Small Bowel Obstruction

Introduction

An IH is defined as the protrusion of abdominal viscera through a peritoneal or mesenteric aperture within the confines of the abdominal cavity. Acquired transmesocolic hernias secondary to abdominal surgery are becoming more common, but congenital transverse transmesocolic hernias remain extremely rare. Given their non-specific symptoms and imaging findings, preoperative diagnosis is particularly challenging.

We herein report a case of congenital transverse transmesocolic hernia in a female patient presenting with SBO and we review the most relevant clinical, imaging and surgical features among the published literature.

Case Presentation

A 77-year-old female patient with history of arterial hypertension, dyslipidemia and a median laparotomy for an emergent cholecystectomy 18 years earlier was admitted in the emergency department with abdominal pain and vomiting for 3 days. She also referred chronic constipation, aggravated in the last few months. A colonoscopy performed 3 years earlier revealed diverticulosis. On physical evaluation her abdomen was tender but with negative Blumberg sign. Laboratorial workup pointed an inflammatory response with leukocytosis (16520/µL), elevated C-reactive protein (4.18 mg/dL) but normal lactate (10 mg/dL). A plain abdominal radiograph obtained at admission demonstrated signs of SBO (Figure 1) and the patient was started on conservative measures with nasogastric drainage and intravenous hydration.

A non-enhanced Computed Tomography (CT) subsequently performed revealed multiple dilated and predominantly fluid-filled small bowel loops (Figure 2) in the right lower quadrant. The plain abdominal radiograph (Figure 1) and the abdominal computed tomography revealed findings highly suggestive of an IH. A congenital transmesocolic hernia of the transverse colon was confirmed on laparotomy with reduction and closure of the defect leading to full recovery of the patient. In this case report, the clinical pictures and radiological features are highlighted together with a review of the literature.
bowel loops abnormally clustered in the upper abdominal quadrants directly abutting the abdominal wall and displacement of the overlying omental fat. It was also noticed an inferior displacement of the transverse colon (green arrow) and the superior mesenteric artery was displaced to the right (orange arrow) with crowding, stretching, engorgement, and displacement of its visceral branches. These findings were consistent with an internal hernia. In addition, subtle signs of bowel ischemia were noticed by the presence of mesenteric edema and intraperitoneal fat stranding. The patient underwent median laparotomy that confirmed a transverse transmesocolic hernia, with almost all the small bowel herniated in the lesser sac, through a dilated angle of Treitz (Figure 3). There were no other findings or evidence of mal-rotation. Bowel viability allowed hernia content reduction and defect closure. Post-operative ileus complicated her stay, but on the 6th post-operative day she was fully recovered and discharged. On follow up the patient denied complaints and clinical examination was innocent.

Discussion

IH incidence is reported between 0.2% to 0.3% of autopsies [1] being responsible for 0.6% to 9.6% of intestinal obstruction [1-9].

The hernial orifice may be a preexisting anatomic structure or a pathologic defect of the mesentery or peritoneum, either acquired or congenital [1,10-12]. Given its rarity, congenital IH classification remains under debate [13,14], but their nomenclature is determined

by the location of its orifice (Table 1) [15-20].

Transmesenteric hernias have become more common due to increased frequency of surgical procedures, especially those with Roux-en-Y loop construction [2,21]. Indeed, acquired transmesenteric hernias are expected in 5% of patients undergoing gastric bypass for morbid obesity, with greater incidence with retrocolic roux limb and unclosed defects [22,23]. In some case series, acquired postsurgical transmesenteric hernia represent up to 57% to 80% of all IH [19,24].

Contrarily, the incidence of congenital transmesenteric defects remains unchanged, around 10% to 15% of reported IH [19,25]. Most series present transmesenteric hernias without specifying their location (small bowel vs. mesocolon) [25] limiting the access to transmesocolic hernia real incidence.

The etiology of congenital transmesocolic hernia remains unclear. In 1919 Pringle suggested that the area of transverse mesocolon to the left of the middle colic vessels would be similar to Treves’ avascular ‘field’ [26,27]. If not the result of developmental thinning/reabsorption of an avascular area during rapid mesenteric lengthening, congenital anomalies like partial regression of the dorsal mesentery might explain the defect [1,27-30]. The increased association of transmesenteric herniation with small bowel atresia further supports the concept of vascular anomalies [10,17].

The herniation process itself might be explained by a pulsion theory (abdominal compression during Valsalva maneuver) or a traction-negative pressure theory, the latter caused by the presence of peptic ulcer [15,26] and an aspiration pump-like action of the diaphragm during respiratory movements [27,31]. The correlation with peptic ulcer disease is not mentioned in reports published after the proton pump inhibitors era, and was not evident in any case of the present review. The propulsive effect of peristalsis eventually forces more loops through the mesenteric defect and the distention of the protruded loops incarcarates the bowel [1].

Loebl first reported transmesocolic hernias in 1844, and until 1949 there were no more than 71 cases in the literature [18,27], the majority located in the transverse mesocolon [26]. From 2000 until 2020 we found 26 cases of congenital transverse transmesocolic hernia in adult population index table. Twenty-four cases in Japanese literature (from 1988 until 2012) were excluded due to linguistic barriers.

Amongst 26 cases, 74% denied previous trauma or abdominal surgery and 26% referred surgeries unrelated to the mesocolon defect.

Although other congenital IH occur more frequently in men (3:2) [3,15,20], transmesocolic hernias have a female preponderance (2.25:1) [18,20,27,31]. In concordance with previous literature, we found a female preponderance with 16 female (62%) and 10 male (38%) cases.

Congenital IH can occur at all ages although with a preference between 4th and 5th decades [20,27,31]. Some authors report that retroperitoneal IH are more frequently encountered in adults, whereas transmesenteric are more common in the pediatric age [12]. Regarding that we excluded pediatric cases, we found an age average of 49 (ranging from 18 to 93), with 65% in their forties or older.

In 88% of the cases the hernia defect was on the left of the middle colic artery and the hernial content was exclusively small bowel in 84%, usually in almost all its extension. In 8% only sigmoid colon was incarcerated and in 8% the distal small bowel and ascending colon had herniated together.

IH may have a wide range of manifestations from asymptomatic to constant vague epigastric pain, intermittent colicky pain to acute abdomen [10]. The pain is frequently postprandial, worsened by large meals, and it can subside spontaneously as a result of intermittent herniation [17,21,24,32].

Abdominal pain was present in 96% of the cases of the present review, associated with nausea and vomiting in 85%. In two patients there was evidence of an abdominal lump. One patient was asymptomatic and the diagnose was made during breast cancer staging.

In 42% there was a history of recurrent complaints of intermittent crampy abdominal pain of occlusive character dating back months or years.

Symptom severity is related to the presence of hernia complication like incarceration, strangulation or volvulus [10,31]. The lack of hernial sac in transmesenteric hernias makes them more prone to have protrusion of considerable lengths of bowel and consequently higher rates of reported volvulus (up to 50%) and ischemia (40%) [1,2,10,21,24,33,34]. In this report volvulus and necrosis incidence was only 12% and 15% respectively.
In patients with symptoms of bowel occlusion, CT should be the first imaging modality. The variable location and lack of encapsulation of hernia content within a limiting hernia sac makes the diagnosis of transmesenteric hernia more difficult, with an average CT accuracy of 77%, sensitivity of 63% and specificity of 76% [21]. Previous studies have identified the following predictor signs of transmesenteric hernia on CT [3,21,35,36]: i) cluster with or without dilatation of small bowel in abnormal position; ii) crowding, stretching, displacement and engorgement of mesenteric vessels; iii) right or left displacement of the main mesenteric trunk lateral to the inferior vena cava or to the aorta respectively; iv) displacement of adjacent structures by mass effect (caudal/dorsal displacement of the transverse colon).

Abnormal bowel-wall enhancement or thickening and mesenteric vessel engorgement or fluid are signs of ischemia [3] and the presence of the whirl sign is highly specific for volvulus [21,24].

The scarcity of this pathology associated with the intermittent and nonspecific character of its clinical symptoms may render the diagnosis extremely difficult with the majority made at surgery or autopsy [20,21,24,25,30].

Even in the presence of suspicious or highly characteristic CT scan images in 77%, in only 23% was the diagnosis made preoperatively.

IH approach should always be surgical, with conservative treatment resulting in 100% mortality [25]. Surgery is most of the times diagnostic and therapeutic. Laparoscopy is an optional though conversion due to limited work space in the presence of dilated bowel is a reality [37-40]. We report a 57% conversion rate out of the 27% conversion rate was 0%, even in the presence of ischemia and resection.

In this review there are 7 reported enterectomies, 4 as result of bowel ischemia (2 as a volvulus consequence). The remaining resections were explained by the presence of stenosis (2 patients) and a mesenteric cyst.

A recent series mortality was exclusively the result of sepsis predominantly with *Pseudomonas aeruginosa* isolates and therefore the authors recommend the use of broad-spectrum antibiotics including anti-pseudomonas regimen [2].

The mortality rate in cases with viable bowel reduction has varied from 0.3 to 6 percent [30] but when strangulation is present, mortality ranges from 30% to 70% in earlier reports [30,42] to 4% to 10% in recent series [1,17,24].

Age (>50), longer time to operation (>3 days), massive necrosis (>1 meter) and postoperative ARDS are statistically significant mortality risk factors. Given its frequent presentation with volvulus and ischemia, transmesenteric hernia has higher mortality rates than other congenital IH [32].

Despite 50% of patients being older than 50 years, the mortality rate was 0%, even in the presence of ischemia and resection. There was no information available on morbidity namely post-operative ileus or nutritional deficiencies/weight loss after bowel resection.

**Conclusion**

Transverse transmesocolic hernia is rare clinical entity with an extremely difficult pre-operative diagnosis. It should be considered in any patient with acute bowel obstruction who does not have an external hernia or a previous history of intra-abdominal surgery. CT with clusters of small-bowel loops in the lesser sac with caudally displaced transverse colon and engorged mesenteric vessels should elicit the diagnosis. The treatment is surgical and consists in hernia reduction and closure of the defect, with a good prognosis.
