Gastric Plication for Repeated Gastric Band Prolapse after Endoscopic Treatment: A Case Report

Kang SH* and Yoo JS

Department of Surgery, Seoul Surgical Hospital, South Korea

Abstract

Background: The Band prolapse complications of laparoscopic adjustable gastric banding (LAGB) can be treated endoscopically. We present two patients with repeated prolapses after endoscopic treatment that required gastric plication treatments.

Methods: From December 2007 to March 2016, 1469 consecutive patients (227 male, 1242 female) underwent LAGB; 56 patients had band prolapses and 16 patients were treated by endoscopy. Among the 16 patients, two cases that showed repeated prolapses could be repaired with gastric plication treatments.

Results: The first case was of a 35-year-old woman who underwent laparoscopic gastric plication due to repeated band prolapse. The second case was of a 43-year-old woman with a history of three episodes of band prolapse underwent gastric plication treatment. The clinical features are discussed.

Conclusions: Gastric plication treatment of recurred band prolapse is an effective and feasible procedure.

Keywords: Endoscopy; Band prolapse; Reduction; Gastric band; Gastric plication

Introduction

Laparoscopic adjustable gastric banding (LAGB) is a simple, safe and effective procedure for treating morbid obesity. However, several complications after LAGB have been reported, such as band erosion, prolapse, gastric perforation, abscess, tube disconnection, port flip down and infection. These complications could be the main cause of failure after LAGB. For this reason, revisional weight-loss surgery after failed LAGB might be considered [1]. Band prolapse is a significant and common late complication after LAGB [2]. We have performed endoscopic treatment of band prolapse as we reported [3]. However, band prolapse occurred repeatedly in two cases. We present two patients with repeated prolapses after endoscopic treatment that required gastric plication treatments.

Case Presentation

Case 1

A 35-year-old woman with BMI (body mass index) 40 underwent LAGB procedure to treat her obesity using the pars flaccida technique with no implications suture, and port placement under the anterior sheath of the rectus abdominis muscle (Figure 1). The patient presented a history of onset of band prolapse 22 months after the LAGB procedure (Figure 2). The symptoms of prolapse were sudden abdominal pain and repeated vomiting. An endoscopic procedure was performed after deflation of the band under intravenous anesthesia. Band prolapse was diagnosed and treated by endoscopy. After a prolapsed stomach pouch was found, we inflated it with air. The prolapsed stomach pouch was gradually reduced as the stomach was inflated with air. The stomach was fully reduced and finally the band returned to its normal position. After reduction, the entire lumen of the stomach was examined to check its normality (Figure 3). However, the patient had the second episode of band prolapse that required endoscopic treatment five months after the first one (Figure 4). We treated it with the same endoscopic technique as above (Figure 5). The patient had recurrence that was treated by the endoscopic reduction technique 13 months after the second episode. The third endoscopic treatment of band prolapse was performed for an hour resulting in failure. She was sent to operating room and underwent laparoscopic reduction with two-row gastric plication (Figure 6,7). The gastric greater curvature was plicated using 2/0 prolen from fundus at the level of diaphragm preserving the His angle to 10cm proximal to the pylorus. It took 70min for the whole procedure with 3 trocars under general anesthesia. The patient was discharged in good condition.
3 days after surgery. Fifteen months later, there was no evidence of recurrence (Figure 8).

**Case 2**

A 43-year-old woman with BMI 42 underwent LAGB procedure to treat her obesity using the pars flaccida technique with no implication suture, and port placement under the anterior sheath of the rectus abdominis muscle (Figure 9). The patient presented a history of onset of prolapse 10 months after the LAGB procedure (Figure 10). The symptoms of prolapse were sudden abdominal pain and repeated vomiting. The endoscopic procedure was performed after deflation of the band under intravenous anesthesia. Band prolapse was diagnosed and treated by endoscopy. After a prolapsed stomach pouch was
found, we inflated it with air. The prolapsed stomach was gradually reduced as the stomach was inflated with air. The stomach was fully reduced and finally the band returned to its normal position. After reduction, the entire lumen of the stomach was examined to check for normality (Figure 11). However, this patient had the second and third episode of band prolapse which required endoscopic treatment 4 months after the first and second reduction respectively (Figure 12 and 13). We treated it with the same endoscopic technique as above (Figure 14 and 15). The patient had the fourth band prolapse one month after the third episode. The endoscopic treatment of band prolapse was performed for an hour resulting in failure. She was sent to operating room and underwent laparoscopic reduction with one-row gastric plication (Figure 16 and 17). The gastric greater curvature was plicated using 2/0 prolen from fundus at the level of diaphragm preserving the His angle to 10cm proximal to the pylorus. It took 75min for this procedure with 3 trocars under general anesthesia. The patient was discharged in good condition 3 days after surgery. Five months later, there was no evidence of recurrence (Figure 18).

**Discussion**

Since its first introduction in 1993, LAGB has been accepted as a reliable surgical option for treating obesity thanks to its safety, minimal invasiveness and effectiveness. However, bariatric surgeons have largely abandoned LAGB since 2008 and the number of
The gastric greater curvature was plicated using 2/0 prolen from fundus at the level of diaphragm preserving the His angle to 10cm proximal to the pylorus. The aim of the plication was restriction of the prolapsed portion of the stomach via folds from its own wall [12]. However, we need long term follow-up to evaluate the efficacy of the gastric plication and endoscopic treatment of the band prolapse.

**Conclusion**

Even though endoscopic treatment of the band prolapse is safe and feasible, two patients with repeated band prolapse were treated with laparoscopic gastric plication technique. We need long-term follow-up to evaluate the efficacy of the gastric plication and endoscopic treatment of the band prolapse.
