Pediatric Appendicitis and Its Management: A Review Article

Volkan Sarper Erikci*
Department of Pediatric Surgery, Sağlık Bilimleri University, Tepecik Training Hospital, Turkey

Abstract

Appendicitis is the most common surgical diagnosis for children who present with abdominal pain to the emergency department. However, there are nonspecific examination findings and variable historical features during its presentation. Diagnosis of appendicitis in the pediatric patient may be challenging for the clinician dealing with these children. It is important to have a high index of suspicion and taking a detailed history and physical examination. In diagnosis of appendicitis, adjunctive studies that may be useful are the white blood cell count, C-reactive protein, urinalysis, ultrasonography and computerized tomography when necessary. When appendicitis is suspected, patients should receive immediate surgical consultation, as well as volume replacement and antibiotics if indicated. The most accurate diagnostic tool is perhaps the serial examinations by the same examiner. With this timely approach it will be possible to prevent the significant morbidity that is associated with delayed diagnoses in younger patients.

Introduction

Acute appendicitis is the most common surgical emergency in children and adolescents. Although uncommon in preschool children, appendicitis may present at any age. The lifetime risk of developing appendicitis is 7% to 8%, with a peak incidence in the teenage years [1]. There are 250,000 cases in the United States annually and the majority occur in children with the ages between 6-10 years. Nearly one-third of children with appendicitis have perforation at the time of surgical treatment. It affects males more frequently than females with male predominance (M:F ratio 3:2). There is a seasonal variation in the occurrence of appendicitis so that presentation of appendicitis is increased in the summer months with perforated appendicitis occurring more frequently in the fall and winter seasons [2]. Despite advances and innovations in fluid resuscitation and antibiotics, appendicitis especially in preschool children may be difficult to diagnose and is still associated with significant morbidity even mortality.

Embryology and Anatomy

As a continuation of the inferior tip of the cecum that becomes visible during the eighth week of gestation, appendix rotates to its final position which is the posteromedial aspect of cecum. According to Treves, there are several variations that can be classified, into four types: type 1, the appendix is of fetal type with a funnel shape, type 2, the appendix originates from the cecal fundus, type 3, the appendix originates dorsomedially out of the cecum (most common type) and type 4, the appendix originates directly beside the ileal orifice [3]. The position of the appendix varies among individuals. According to a study comprising 10,000 cases, five positions can be identified [4]: ascending appendix in the retrocecal recess in 65% of cases (most common), descending appendix in the iliac fossa in 31% of cases, transverse appendix in the retrocecal recess in 2.5% of cases, paracecal and preileal ascending appendix in 1% of cases and paracecal and postileal ascending appendix in 0.5% of cases. During surgical treatment it is important to distinguish if the appendix is non-fixed (appendix libera) or fixed (appendix fixa). With an average length of 8 cm, the size of appendix varies from 0.3 cm to 33 cm and its diameter of ranges from 5 mm to 10 mm. The blood comes form appendiceal branch of the ileocolic artery. There are a few submucosal lymph follicles present at birth and these increase to nearly 200 by the age of 12 years and the number of these lymph follicles decreases after the age of 30.

Etiology and Pathogenesis

Obstruction of the appendiceal lumen is usually the first factor that starts the illness. If unresolved, this obstruction leads to vascular congestion, ischemic necrosis and subsequent...
infection. Inspissated fecal material or a fecalith are the most common causes that lead to appendiceal luminal obstruction. Other causes of obstruction include lymphoid follicle hyperplasia, foreign bodies, carcinoid or other tumors and rarely parasites. Fecaliths are found in approximately 40% of cases of acute appendicitis, 65% of cases of gangrenous appendicitis, and approximately 90% of cases of perforated appendicitis. As the appendiceal mucosa continues to secrete the mucus after occlusion of the appendix lumen, this leads to a rapid increase of intraluminal pressure. Secretion of as little as 0.5 mL leads to an increase of pressure of approximately 45 mmHg according to the law of Laplace [5]. This phenomenon also explains the rapid perforation of appendix within a few hours of inflammation. For this reason all the patients with suspected acute appendicitis need hospitalization and close clinical monitoring if appendectomy is not to be performed immediately. Distention stimulates nerve endings of visceral afferent pain fibers and leads to a dull, diffuse mid-abdominal pain that cannot be easily located by the children. As the distention increases it causes reflex nausea and vomiting and once the inflammatory process has involved the serosal part of the appendix and parietal peritoneum, the characteristic finding of shift of the pain from periumbilical area to the right lower abdominal quadrant occurs. Impaired blood supply leads to compromise of the appendiceal mucosa allowing bacterial invasion of the deeper locations. Absorption of bacterial toxins and necrotic material causes fever, tachycardia, and leukocytosis. As the pressure increases, finally perforation occurs usually through the infarcted areas. Although in some patients the disease may spontaneously resolve, untreated obstruction of the appendiceal lumen usually leads to gangrene and perforation.

**Clinical Presentation**

Although appendicitis can affect any age group, it is extremely rare in neonates and infants. Older children present clinical signs and symptoms which are quite variable in pattern and order of appearance. As a first symptom pain usually begins as a dull and vague pattern at the periumbilical area but with time it may localize to the right lower quadrant. Children usually report a gradual increase in pain intensity as the disease progresses. The anatomical variability in the locations of appendix vermiformis (i.e., retrocecal, pelvic, preileal) is common and may alter pain symptoms accordingly. Pelvic or retrocecal appendicitis may only present with right lower quadrant pain without periumbilical pain. Flank pain and referred testicular pain are also common symptoms in children with pelvic or retrocecal appendicitis. If the inflamed appendix has a close relationship with ureter or bladder, it may produce symptoms associated with urinary tract such as urinary frequency, dysuria, urinary retention and bladder distention. It is traditionally known that severe gastrointestinal symptoms that develop prior to the onset
of pain usually indicate a diagnosis other than acute appendicitis. On the other hand mild gastrointestinal symptoms such as decreased appetite, indigestion and changes in bowel habits may develop within a few hours of pain onset. Typically patients with uncomplicated appendicitis have low-grade fever. Fever above 38.6 degrees, tachycardia, and leukocytosis develop as a consequence of mediators released by ischemic tissues, white blood cells and bacteria. Children with appendicitis avoid movement and tend to lie in bed with their knees flexed. Hyperesthesia of the skin can be elicited by touching the skin of the patient with a stethoscope. Abdominal tenderness associated with appendicitis varies with the stage of the disease and location of the inflammed vermiform appendix. Classical "McBurney's point" that is the area one-third the distance from anterior superior iliac spine to the umbilicus, is the most common site of maximal tenderness that is found on the abdominal wall. Rectal tenderness may be observed in patients with pelvic appendicitis. In the case of malrotation the tenderness due to appendicitis may occur on unusual locations which may be away from the usual site. There are some clinical signs that should produce high index of suspicion regarding appendicitis. These are namely, "Rovsing's sign" (palpation of left lower quadrant producing tenderness over the right iliac fossa) and it is a reliable indicator of appendicitis in childhood. The "poas sign" that is commonly observed in retrocecal appendicitis and the "obturator sign" suggesting pelvic appendicitis are the other useful clinical signs that should prompt clinician to diagnose acute appendicitis early. The physical examination of a patient suspected to have appendicitis (especially pelvic appendicitis) is missing without rectal exam which may reveal a tender palpable mass or abscess. Differential diagnosis of acute appendicitis has a wide spectrum of diseases and includes gastroenteritis, inflammatory bowel disease such as Crohn's disease, cholelithiasis, mesenteric adenitis, pancreatitis, peptic ulcer disease, Meckel's diverticulitis, constipation, intussusception and many other disease states (Table 1). Systemic diseases including diabetic ketoacidosis, lupus erythematosus, hemolytic uremic syndrome, sickle cell crisis, Henoch-Schönlein purpura, and parasitic infections may produce symptoms suggesting acute appendicitis. In females with certain situations such as ectopic pregnancy, ovarian torsion, developmental ovarian cysts and pelvic inflammatory disease a misdiagnosis of acute appendicitis may cause unnecessary surgical interventions. Pneumonia particularly affecting the right lower lobe, urinary tract diseases such as renal or ureteric stones, pylonephritis, urinary tract infections can also mimic acute appendicitis. Children with cystic fibrosis have a higher incidence of acute appendicitis. A neonate with appendicitis should increase the suspicion of Hirschsprung's disease in the mind of the clinician.

**Diagnosis**

History and physical examination is important in diagnosing appendicitis in children. The most accurate diagnostic tool is perhaps the serial examinations by the same examiner while the child is cooperative with the clinician. Before starting the palpation of the abdomen, the child should be asked to point out the location of the abdominal pain. Cutaneous hyperesthesia is often an early finding derived from the T10 to L1 nerve roots. There is a mild abdominal pain that can not be localized at the early stages of the disease. As the disease progresses, localized tenderness is most often found at the McBurney's point. Rectal tenderness may be observed in pelvic appendicitis and tenderness midway between the twelfth rib and the posterior superior iliac spine is detected in patients with retrocecal appendicitis. If malrotation accompanies the disease, position of the inflammed appendix has a role in the changing locations of tenderness. Peritonitis ensues as the disease progresses to perforation with generalized abdominal rigidity. Rebound tenderness is seldom necessary for diagnosis and may cause unnecessary discomfort for children. Routine rectal examination in diagnosing appendicitis in childhood is a matter of debate and if other signs suggest to the diagnosis of appendicitis, rectal examination may be unnecessary. But it is especially helpful diagnostic tool for patients with pelvic appendicitis with abscess or those with ureter or adnexal pathologic conditions. It should be re-emphasized that when the diagnosis is unclear, with the aid of serial physical examinations, it is possible to decrease the number of unnecessary surgical interventions that may increase risk to the patient if performed. This issue is very important because in a recent study, among the children undergoing appendectomy, 6.3% in Canada and 4.3% in the United States, are subsequently found to have a normal appendix and it has been reported that a misdiagnosis of appendicitis that leads to negative appendectomy ranges up to 30% [6]. The most often used laboratory aids to diagnose appendicitis are White Blood Cell (WBC) count, Absolute Neutrophil Count (ANC), and C-Reactive Protein (CRP) but these tests alone are not helpful or predictive. Leukocyte count above 10,000 is observed in greater than 90% of children with acute appendicitis. But normal WBC count may also be observed in 5% of patients with appendicitis. A shift to left is a usual finding and is of better diagnostic value compared to ANC. A neutrophil-lymphocyte ratio of greater than 3.5 has a greater specificity and sensitivity in diagnosing appendicitis. There are numerous appendicitis scoring systems that have been suggested as an adjunct to diagnosis of appendicitis. Two systems namely the Alvarado score and the Pediatric Appendicitis Score (PAS) have been extensively studied but do not have 100% sensitivity and specificity in the diagnosis of appendicitis and they do not replace an experienced pediatric surgeon [7-9]. It has been documented that a pediatric surgeon can differentiate appendicitis from other abdominal disorders with 92% accuracy [10]. Urinalysis is helpful in differentiating urinat tract infections and urolithiasis from appendicitis. However when inflammed appendix is close proximity with ureter, hematuria and pyuria may also be detected even there is not urinary tract infection or urolithiasis. Imaging studies may be useful in cases where the diagnosis is equivocal and plain film radiography may have a value. The incidence of presence of a fecalith that can be seen on direct roentgenograms ranges from 10% to 20% of cases with appendicitis and this ratio increases accordingly in patients with complicated appendicitis. Other subtle plain film findings are; sentinel loop in the right lower quadrant, lumbar scoliosis with a concavity to the right lower quadrant, mass effect due to pelvic abscess, loss of psoas shadow, obliteration of the proportionate fat stripe. It is necessary to have a chest radiograph for ruling out right lower lobe pneumonia. Although it is usually useful tool in the management of children with intussusception, barium enema may rarely be performed in children suspected of having appendicitis. Barium enema findings in appendicitis include; incomplete filling of the appendix, extrinsic mass effect on the cecum or terminal ileum and irregularities of the appendiceal lumen. With a sensitivity of 85% and specificity of greater than 90%, Ultrasonography (US) is an effective diagnostic tool if performed especially by skilled hands. Sonographic criteria for the diagnosis of appendicitis is demonstration of a noncompressible appendix that is 7 mm or larger in diameter, a wall thicker than 2 mm, or an irregular wall that is rigid, and lacks peristalsis. Other findings that may be helpful in diagnosing appendicitis include absence of air in the appendicale lumen, perialappendiceal fat changes, visible...
appendicolith, complex mass, mesenteric lymph nodes and free fluid
[11]. Advantages of US include lack of sedation, contrast agents and
radiation during procedure [12]. On the other hand there are also
disadvantages regarding US that include need for operator experience,
a lack of regular availability during off hours, difficult visualization
especially in obese children [13]. Computed Tomography (CT) is also
useful for inconclusive cases. It combines the advantages of many
other imaging modalities, including rapid acquisition time and a lack
of operator dependency [14]. The findings of an enlarged appendix
(>6 mm), appendiceal wall thickening (>1 mm) and appendiceal wall
enhancement are useful diagnostic criteria that are found in CT.
Comparing US and CT in diagnosing appendicitis in children, it has
been proposed that US is more specific and CT is more sensitive [15].
Magnetic Resonance Imaging (MRI) has a high diagnostic accuracy
for appendicitis but it has certain disadvantages including limited
utility, lack of availability in many centers, lengthy acquisition time,
need for sedation or anesthesia and high cost compared to other
imaging modalities [15]. It should be re-emphasized again that these
radiological diagnostic modalities, if used routinely, cause hospital
resource utilization and delay in surgical treatment. Besides potential
cancer risk associated with ionizing radiation from CT should also be
kept in mind and these imaging tools should be reserved for patients
with uncertain findings related to appendicitis.

**Treatment**

There are several treatment modalities of appendicitis with a wide
spectrum ranging from nonoperative management to open or
laparoscopic surgical interventions. Nonoperative management of
appendicitis has been an interest for many scientists and several trials
demonstrated successful nonoperative management of acute
appendicitis in 70% to 85% of cases at the 1-year follow-up [16,17].
On the other hand it has been stated in another meta-analysis that the
combined failure and recurrence rates in nonoperative patients made
this approach less effective overall [18]. Regarding the nonoperative
management of pediatric appendicitis, children revealed a success
rate ranging from 75% to 80% and in a recent study up to 89% success
rate of nonoperative management has been reported [19,20]. It has
also been demonstrated that compared to surgically treated patients,
nonoperative patients reported higher quality-of-life scores at 30 days
[20]. In some situations nonoperative management of appendicitis
may be unsuccessful and one of these predictors of failure of
nonoperative management has been reported to be presence of
appendicolith on imaging studies [21]. Another study on the
nonoperative management of uncomplicated appendicitis
demonstrated a failure rate of 60% and was halted early [22]. To sum
up, although there is not a consensus in which patients should receive
nonoperative treatment, for carefully selected children with acute
appendicitis it is possible and should be kept in mind. In the surgical
management of appendicitis, the goals are to minimize complications
and cost, decrease patient anxiety, and improve quality of life.
Although according to the traditional thinking that emergent
appendectomy should be performed at the time of diagnosis, immediate surgical intervention is not considered mandatory for
most patients. Many centers dealing with pediatric appendicitis now
perform appendectomies in the day time for patients presenting at
night time [23]. With this approach, the stress that occurs in the
overnight appendectomies for both the children, their families and
the surgeon is avoided. Complication and perforation rates are
similar for patients undergoing surgery within 6 hr of admission
compared to those undergoing surgery between 6 hr to 16 hr after
admission to hospital. The majority of pediatric surgeons perform
appendectomy within 8 hr after admission. Nevertheless after an
expedient resuscitation, all the patients with appendicitis must
undergo timely surgical exploration. Initial therapy starts with
intravenous fluid resuscitation, broad spectrum antibiotic coverage
and keeping the patient nothing per mouth. There is a trend toward
decreasing the duration of antibiotic therapy. The recommended
duration of antibiotic therapy is preoperative plus 24 hr postoperative
period for simple appendicitis and 10-day course of ampicillin,
gentamicin, and metronidazole or clindamycin for complicated
appendicitis and these therapies are known as gold standard. On the
other hand it has been documented that bacteriologic epidemiology
of appendicitis shows that both piperacillin/tazobactam and cefoxitin
have been shown to be at least as effective as the triple-drug regimen,
and may also decrease length of hospital stay and costs [24].
Nevertheless, total length of antibiotic therapy should be determined
by the clinical condition of the patient (resolution of fever, pain,
bowel function) and WBC count [25]. Surgical treatment includes
open technique and laparoscopic appendectomy. Except for specific
situations including any surgical intervention having right lower
quadrant incision such as Meckel’s diverticulectomy or intussusception
reduction, incidental appendectomy is no longer performed routinely and does not have any benefit. In traditional
appendectomy that was first described by McBurney, a transverse or
oblique lower right quadrant incision is performed and by splitting
the muscles, abdominal cavity is entered and mesappendix is divided
followed by excision of the appendix at its base [26]. There are
different techniques of management of appendiceal stump including
simple ligation, ligation and inversion using a purse-string, or a pure
inversion without ligature. The choice of stump management directly
relates to attending surgeon. Since the first description of endoscopic
appendectomy in 1983, laparoscopic appendectomies are being
performed more commonly nowadays and today laparoscopic
appendectomies have largely replaced the open surgery up to a
percentage of 91% [27]. There are several different operative
approaches in the laparoscopic management of appendicitis including
three-port laparoscopic intervention, transumbilical laparoscopic
appendectomy, single port/incision techniques. Advantages of
laparoscopy include shorter hospital stay, decreased postoperative
pain and wound complications, ability to diagnose inconclusive cases,
surgical ease in obese patients, and faster recovery after surgery.
On the other hand there are disadvantages of laparoscopic approach
which are a higher cost of equipments, longer operative time, time
needed for learning curve in laparoscopy education, experience
required for surgeons and increased incidence of intra-abdominal
infection. It has been previously stated that complication rates are
lower compared to open appendectomy except that the postoperative
intra-abdominal abscess rate is higher with laparoscopic approach
[28]. But this this topic seems to be changed as it has been found in
the meta-analysis and multi-institutional reviews that there are no
differences in intra-abdominal abscess rates following laparoscopic
appendectomy compared to open surgical interventions for appendicitis
[29,30]. To sum up, laparoscopy is safe and effective means of
performing an appendectomy in the treatment of pediatric
appendicitis. If a normal appendix is found at laparotomy (5% to 15%
of cases), the abdomen is systematically inspected for evidence of
inflammatory bowel disease, a Meckel’s diverticulum, mesenteric
adenitis, peptic ulcer disease. In females fallopian tubes and ovaries
should be identified and inspected for ovarian cysts or torsion, and
for rare occurrence of isolated tubal torsion and pelvic inflammatory
The overall morbidity in children with complicated appendicitis is complicated appendicitis has dropped dramatically to nearly zero. The incidence of infectious complications, the mortality rate for subhepatic appendicitis, respectively. Sepsis and multisystem dehiscence, postoperative intestinal obstruction, prolonged ileus, wound infections, intra-abdominal abscesses, bowel obstructions, and reoperations [33]. On the other hand early appendectomy, compared to interval appendectomy, significantly reduced the time away from normal activities [33]. Opponents to interval appendectomy suggest that it is unnecessary because only 14% of patients have recurrent symptoms, and after initial diagnosis, recurrence is uncommon within 2 years. Nevertheless, it is very important that if an operation is to be performed, great care should be taken to avoid damage to adjacent structures such as small intestine, the fallopian tubes, ovaries and ureters. In the case of well localized periappendiceal abscess or phlegmon, after a prolonged antibiotic therapy (2-3 weeks) CT or sonographic guided percutaneous abscess drainage may be an other option in the treatment of these children. The current standard for patients presenting with a palpable abdominal mass who are usually young children with perforation, is conservative management with interval appendectomy after 8 to 12 weeks.

**Complications**

Complication rates after appendectomy differ greatly with regard to the severity of the appendicitis. Complications are rarely seen after simple appendicitis, but are more often seen in children with complicated appendicitis. Wound infection is the most common complication after appendectomy. With the world-wide usage of antibiotics, the rate of wound infection has fallen from 50% to less than 5%, even in complicated appendicitis. Other complications of appendicitis include intra-abdominal abscess formation, wound dehiscence, postoperative intestinal obstruction, prolonged ileus, and rarely enterocutaneous fistula. It has been reported that the postoperative risk of an intra-abdominal abscess is approximately 20% for children with perforated appendicitis, and the risk for children with simple appendicitis to develop an abscess is less than 0.8% [31]. Tubal infertility and pylephlebitis may also be observed after surgical treatment for complicated appendicitis such as pelvic and subhepatic appendicitis, respectively. Sepsis and multisystem organ failure can occur in young children with a prolonged illness before definite diagnosis. As the antibiotics have markedly decreased the incidence of infectious complications, the mortality rate for complicated appendicitis has dropped dramatically to nearly zero. The overall morbidity in children with complicated appendicitis is less than 10%.

**Conclusion**

Appendicitis occurs most commonly between the ages of 10 to 11 years. The classical signs and symptoms of migrating pain to the right lower quadrant, rebound tenderness are present in less than half of the children presenting with appendicitis. When the diagnosis is certain, the combination of evaluation and prompt surgical intervention is all that is needed. If the diagnosis of appendicitis is inconclusive, a period of observation including usage of scoring systems for evaluating the patient followed by radiological imaging modalities becomes a matter of necessity rather than of choice. As CT scans increase radiation exposure, US should be the choice of imaging modality in these patients. Laparoscopic approaches now constitute more than 90% of appendectomies in these patients even in cases with perforated appendicitis. In selected cases, appendicitis can be managed nonoperatively. Although provided that care is given by experienced clinicians and institutions, the best outcome for children with appendicitis may be anticipated, a small number of patients may still develop complications following surgical treatment of appendicitis. Nevertheless, the long-term outcome for the majority of children who undergo appendectomy is very good.
